Anisotropic optical absorption properties of single-walled carbon nanotubes (SWNTs) are determined from the measurements of a recently developed vertically aligned SWNT film grown on an optically polished quartz substrate. In addition to the inter-subband absorption below 3 eV, we present for the first time the remarkable polarization dependence of absorption peaks at 4.5 eV and 5.25 eV. Furthermore, the important relevance of these absorption peaks of SWNTs to the optical properties of graphite is revealed. Finally, a method for determining a nematic order parameter for an aligned SWNT film by separating the collinear absorption peak at 4.5 eV from other transition dipoles is introduced, followed by the determination of intrinsic optical absorption cross-section of the SWNTs for 0.5 - 6 eV.

The vertically aligned SWNT film was grown on both sides of a quartz substrate [1], using the alcohol CCVD method [2]. Figure 1 shows a cross-sectional FE-SEM image of the sample used in the measurements, which has a thickness of 2.1 μm per side. Figure 2a and 2b show polarized absorption spectra from the aligned SWNT film for s- and p-polarized light, respectively, normalized by the \( \cos^2 \theta \) increment of the light path length. The angle \( \theta \) was changed from 0° to 45° in increments of 7.5°. Most noticeable is the polarization dependence of the peaks at 4.5 and 5.25 eV, whose origins and characteristics toward light polarizations have been investigated in detail and to be presented in the symposium.
